RESEARCH ARTICLE

10.1029/2024JD041368

Key Points:

- *n*-Alkanes and PAHs can show stronger sorption to particulate matter (PM) than in the simulation based on the equilibrium absorptive partitioning theory
- Combining absorption and adsorption mechanisms can improve the agreement between measured and predicted partitioning coefficients
- The sorption of *n*-alkanes and PAHs on PM is less liquid-like in Denver than in Nanjing

Abstract The concentration data of semi-volatile *n*-alkanes and PAHs in the gas phase and in PM_{2.5} were obtained from Nanjing and Denver. First, the gas-particle partitioning coefficients of the target compounds were calculated and compared with the predictions based on the equilibrium absorptive partitioning theory. Although the vapor pressure (p°_L) estimation method was selected to improve the agreement between measured and predicted partitioning coefficients, *n*-alkanes in Denver and PAHs in both cities exhibited stronger sorption to PM_{2.5} than predicted. By including the adsorption mechanism, the average logarithms and temporal variations of the partitioning coefficients were well simulated in both Nanjing and Denver. The partitioning of *n*-alkanes in Nanjing can be primarily explained by the absorption mechanism, while the adsorption mechanism dominates that for *n*-alkanes in Denver and PAHs in both cities. To obtain an optimal simulation, the p°_L of *n*-alkanes and PAHs was estimated using the SPARC and SIMPOL—two group contribution methods, respectively, and the difference between desorption and vaporization enthalpies was set between 2 and 3 kcal mol⁻¹ for *n*-alkanes in Denver and PAHs in both cities. Therefore, the estimation of p°_L and surface adsorption should be carefully considered when parameterizing the gas-particle partitioning of non-polar organic compounds in future field and modeling studies.

Plain Language Summary The gas-particle partitioning of semi-volatile organic compounds is an important atmospheric process that can affect their fate and transport. The concentrations of selected *n*-alkanes and PAHs significantly present in both the gas and particulate phases in Nanjing and Denver were obtained from our previous studies. When absorption in particulate organic matter (OM) was assumed as the dominant mechanism, the gas-particle partitioning of *n*-alkanes in Denver and PAHs in both cities cannot be well explained. When both absorption in the particulate OM phase and surface adsorption were considered, good agreement between measured and predicted partitioning coefficients could be obtained for all target compounds by selecting an appropriate method to estimate the vapor pressure (p°_L) and fixing the difference between desorption and vaporization enthalpies. In previous studies, the simulated partitioning coefficients differed by orders of magnitude from the measured values, partly due to the ignorance of p°_L estimation method selection and surface adsorption.

1. Introduction

Semi-volatile organic compounds (SVOCs) have a wide range of vapor pressures (10⁻¹⁴ to 10⁻⁴ atm; Weschler & Nazaroff, 2008). The partitioning between the gas and condensed phases of SVOCs plays an important role in influencing their fate and transport in the atmosphere (Bidleman, 1988; Liang et al., 1997) and is also a pivotal process for the formation of secondary organic aerosols (SOA) through photochemical reactions and reactive uptake of gaseous oxygenated intermediates (Donahue et al., 2006; Hallquist et al., 2009). Early studies parameterized the gas-particle partitioning of SVOCs based on the concentrations of particulate matter (PM) and individual organic compounds in ambient air (Pankow & Bidleman, 1992; Yamasaki et al., 1982):

$$K_p = \frac{F/TSP}{A} \quad (1)$$

where K_p ($\text{m}^3 \mu\text{g}^{-1}$) is the partitioning coefficient, TSP ($\mu\text{g m}^{-3}$) is the mass concentration of the total suspended PM, and F (ng m^3) and A (ng m^3) are the particle and gas phase concentrations of the target compounds, respectively. Pankow (1994a, 1994b) developed a partitioning model to predict the contributions of absorption and adsorption mechanisms to K_p :

$$K_p = \frac{1}{p_L^0} \left[N_s a_{\text{TSP}} R T e^{(Q_1 - Q_v)/RT} + \frac{f_{\text{OM}} R T}{10^6 \text{MW}_{\text{OM}} \zeta_{\text{OM}}} \right] \quad (2)$$

where the first term in the brackets depicts the physical adsorption on the particle surfaces, and the second term represents equilibrium absorptive partitioning towards the organic matter (OM) phase in PM. In the adsorption term, N_s (mol cm^{-2}) is the surface concentration of adsorption sites, a_{TSP} ($\text{m}^2 \text{g}^{-1}$) is the specific surface area of total suspended PM, R is the gas constant (e.g., $8.21 \times 10^{-5} \text{m}^3 \text{atm mol}^{-1} \text{K}^{-1}$), T is the temperature (K), Q_1 and Q_v (kJ mol^{-1}) are the enthalpies of desorption and vaporization, respectively. For the absorption mechanism, f_{OM} is the mass fraction (%) of the OM phase in the total PM, MW_{OM} (g mol^{-1}) is the mean molecular weight (MW) of the OM phase, ζ_{OM} is the activity coefficient of a given compound in the OM phase on the mole fraction scale. In Equation 2, p_L^0 (atm) is the vapor pressure of each pure compound at the temperatures during sampling. The equilibrium absorptive partitioning has been proposed as the dominant mechanism (Liang et al., 1997; Liang & Pankow, 1996; Mader & Pankow, 2002) and applied to predict the SOA yield in the smoke chamber and the ambient (Beardsley & Jang, 2016; Odum et al., 1996; Zhang et al., 2022). The measured and predicted partitioning coefficients based on the equilibrium absorption mechanism can be calculated as follows

$$K_{\text{p,OM}}^{\text{m}} = \frac{K_p}{f_{\text{OM}}} = \frac{F/M_{\text{OM}}}{A} \quad (3)$$

$$K_{\text{p,OM}}^{\text{t}} = \frac{RT}{10^6 \text{MW}_{\text{OM}} \zeta_{\text{OM}} p_L^0} \quad (4)$$

where $K_{\text{p,OM}}^{\text{m}}$ and $K_{\text{p,OM}}^{\text{t}}$ are measured and predicted absorptive partitioning coefficients ($\text{m}^3 \mu\text{g}^{-1}$), and M_{OM} ($\mu\text{g m}^{-3}$) is the concentration of the OM phase in PM.

The reactions of secondary organics in the condensed phase and their absorptive partitioning to aerosol liquid water (ALW) are potential reasons for the underestimation of SOA production by assuming that particulate OM is the only absorbing phase under ideal mixing conditions (Barsanti et al., 2013; Daumit et al., 2016; Healy et al., 2008; Kampf et al., 2013; Pye et al., 2017; Yu et al., 2021). In contrast, the base-10 logarithms of $K_{\text{p,OM}}^{\text{m}}$ ($\lg K_{\text{p,OM}}^{\text{m}}$) and p_L^0 ($\lg p_L^0$) of non-polar SVOCs (e.g., PAHs) are strongly correlated with regression slopes fluctuating around -1.0 (Gou et al., 2021; Liang et al., 1997), suggesting that their gas-particle partitioning is a temperature-controlled process associated with the OM phase in PM. Therefore, the agreement between $K_{\text{p,OM}}^{\text{m}}$ and $K_{\text{p,OM}}^{\text{t}}$ for each SVOC may strongly depend on the reasonableness of p_L^0 estimation. In addition, the effect of adsorption on particle surfaces cannot be excluded under certain circumstances. For example, polycyclic aromatic compounds (PAHs) exhibit stronger sorption than n -alkanes at a given p_L^0 possibly due to the π - π interactions between PAHs and PM surfaces (Cousins & Mackay, 2001; Liang & Pankow, 1996; Zhu et al., 2004). Except for the influences of p_L^0 estimation and surface adsorption, the discrepancies between $K_{\text{p,OM}}^{\text{m}}$ and $K_{\text{p,OM}}^{\text{t}}$ observed in previous studies could also be caused by measurement artifacts, variations in MW_{OM} and ζ_{OM} , non-ideal mixing, etc (Cappa et al., 2008; Chang & Pankow, 2010; Pankow & Bidleman, 1992; Pankow & Chang, 2008; Wang et al., 2015).

In this work, measurement data of selected n -alkanes and PAHs in the gas phase and in $\text{PM}_{2.5}$ were obtained from Nanjing, China, and Denver, United States. The measured and predicted partitioning coefficients of these SVOCs were calculated based on Equations 1–4. For the prediction of partitioning coefficients, the p_L^0 values of individual compounds were estimated by three methods, and three Q_1 – Q_v values were considered for the evaluation of

the adsorption mechanism. The study results will improve our understanding and simulation of the gas-particle partitioning of non-polar SVOCs in the atmosphere.

2. Methods

2.1. Measurement Data Preparation

The measurement data for *n*-alkanes and PAHs in the cities of Nanjing and Denver were obtained from Gou et al. (2021) and Xie et al. (2014). In these two studies, gaseous and particulate SVOCs were measured using a similar method. In brief, ambient air was drawn through two stacked pre-baked quartz filters and a sandwich cartridge of polyurethane foam (PUF)/XAD-4 resin/PUF (PXP) by a medium-volume sampler equipped with a 2.5 μm cut impactor or cyclone. Non-polar SVOCs in filter and PXP samples were extracted with dichloromethane and analyzed with an Agilent 7890B gas chromatograph (GC) coupled to an Agilent 5977B mass spectrometer (MS). Total organic carbon (OC) and elemental carbon (EC) on the filter samples were measured using a thermal optical ECOC analyzer. The upper filter (Q_f) was used to determine the $PM_{2.5}$ mass through gravimetric analysis and particle-phase organics. SVOCs on the backup filter (Q_b) were assumed to be contributed equally by gaseous adsorption (“blow on,” positive artifact) and evaporative losses from Q_f (“blow off,” negative artifact). The PXP cartridge was installed for the adsorption of gaseous SVOCs. Therefore, in this work, the particle phase concentrations of the target compounds were defined as their concentrations in Q_f samples, and the total concentrations of the target compounds in Q_b and PXP samples were treated as their gas phase concentrations.

The organic compounds with extremely high ($>10^{-6}$ atm) or low p_L^o ($<10^{-10}$ atm) exist almost exclusively in one phase (gas or particle phase), and their concentrations in the other phase can be very low and subject to great uncertainty. Therefore, the *n*-alkanes and PAHs selected for analysis in this work have significant concentrations in both the gas and particle phases. Information on the selected *n*-alkanes (6 species, carbon number = 18–23) and PAHs (5 species, MW = 178–228) is provided in Table 1. A total of 102 pairs of 12-hr gas-phase and particle-phase samples of the above compounds were obtained at a suburban site in northern Nanjing from 28 September 2018 to 29 September 2019 (Gou et al., 2021); 50 pairs of 24-hr samples of the same species were obtained at an urban site in Denver from 28 August 2012 to 25 July 2013 (Xie et al., 2014). The average concentrations of *n*-alkanes and PAHs in the gas and particulate phases and their average particle-phase fractions ($F\%$) in Nanjing and Denver are summarized in Table 2. As the target compounds were not detected in the particle and/or gas phase for some sample pairs, especially for low volatile species (e.g., *n*-C23, BaA, and CT) in the gas phase during the cold period, these observations were not included in the calculation of $F\%$ and partitioning coefficients.

2.2. Calculations of the Partitioning Coefficients

The $K_{p,OM}^m$ values of the target compounds were calculated using Equation 3, where M_{OM} was defined as the concentration of OC in $PM_{2.5}$ multiplied by 1.6 (Turpin & Lim, 2001), and their $K_{p,OM}^t$ values were calculated using Equation 4. For each sample, the p_L^o values of the target compounds were adjusted based on the average temperature:

$$p_L^o = p_L^{o,*} \exp \left[\frac{Q_v^*}{R} \left(\frac{1}{298.15} - \frac{1}{T} \right) \right] \quad (5)$$

where $p_L^{o,*}$ and Q_v^* are the subcooled liquid vapor pressure (atm) and the enthalpy of vaporization (kJ mol^{-1}) at 298.15 K. To evaluate the impact of p_L^o estimation on the agreement between $K_{p,OM}^m$ and $K_{p,OM}^t$, $p_L^{o,*}$ was predicted using three methods, including the U.S. Environmental Protection Agency's Toxicity Estimation Software Tool (TEST; EPA, 2022) and the group contribution methods (GCMs) SPARC (<http://archemcalc.com/sparc-web/calc/>) and SIMPOL (Pankow & Asher, 2008; Table 1). Literature $p_L^{o,*}$ values from indirect measurements based on the temperature dependence of GC retention times are also listed in Table 1. Xie et al. (2013) have tested the sensitivity of $K_{p,OM}^t$ to changes in temperature (276.5–297.6 K), MW_{OM} (50–300 g mol^{-1}), ζ_{OM} (0.5–1.5), and OM/OC ratios (1.3–1.6). Since p_L^o increased exponentially with temperature (Equation 5) and varied by more than an order of magnitude within 20 K, $K_{p,OM}^t$ is most sensitive to ambient temperature. Due to the large variability in ambient temperature during sampling (Table 2) and $p_L^{o,*}$ values across the three estimation methods (Table 1), the selection of $p_L^{o,*}$ estimation method was prioritized in the prediction of $K_{p,OM}^t$, and the

^aGou et al. (2021). ^bXie et al. (2013, 2014). ^cChickos and Hanshaw (2004) and references therein. ^dHaftka et al. (2006) and references therein.

values of other parameters in Equation 4 were set in accordance with previous studies ($MW_{OM} = 200 \text{ g mol}^{-1}$ and $\zeta_{OM} = 1.0$; Barsanti & Pankow, 2004; Williams et al., 2010; Xie et al., 2013, 2014). Due to the narrow range of literature $p^{o,*}_L$ and Q^*_v (Table 1), their midranges were used for the prediction of $K_{p,OM}$ for comparison.

To understand whether the inclusion of the adsorption mechanism can improve the simulation of the gas-particle partitioning, measured and predicted K_p values ($K^m_{p,PM_{2.5}}$ and $K^t_{p,PM_{2.5}}$) were calculated for comparison using Equations 1 and 2, where the mass concentration of TSP was replaced by that of $PM_{2.5}$. As shown in Table S1 in Supporting Information S1, N_s varied within an order of magnitude among different PM types (2.33×10^{-10} – $9.47 \times 10^{-10} \text{ mol cm}^{-2}$). Although the a_{PM} value showed great variability across different PM sizes and types, the a_{PM} value of $PM_{2.5}$ ($a_{PM_{2.5}}$) agreed well in different field studies ($\sim 10 \text{ m}^2 \text{ g}^{-1}$). In Equation 2, the first term increases exponentially with the Q_l-Q_v value, which was initially used to fit measured K_p by assuming an equilibrium adsorption mechanism based on field data of organochlorines and PAHs and varied between 1 and 3 kcal mol⁻¹ (Bidleman et al., 1986; Bidleman & Foreman, 1987; Pankow, 1987; Yamasaki et al., 1982, 1984). When the absolute Q_l-Q_v value is close to 0, nearly liquid-like sorption is occurring. At $T = 273 \text{ K}$, the first term in the brackets of Equation 2 increases by more than two orders of magnitude, with the Q_l-Q_v value varying between 0 and 3 kcal mol⁻¹. So, three Q_l-Q_v values (0, 1.5, and 3 kcal mol⁻¹) were tested in this work for the comparison of $K^m_{p,PM_{2.5}}$ and $K^t_{p,PM_{2.5}}$. For the calculation of $K^t_{p,PM_{2.5}}$, f_{OM} was the mass fraction of OM in $PM_{2.5}$; an N_s value of $4 \times 10^{14} \text{ cm}^{-2}$ (or $6.64 \times 10^{-10} \text{ mol cm}^{-2}$), which lies between the values for TSP and soot particles, and an $a_{PM_{2.5}}$ value of $10 \text{ m}^2 \text{ g}^{-1}$ were chosen.

3. Results and Discussion

3.1. $\lg K^m_{p,OM}$ Versus $\lg K^t_{p,OM}$ Within Groups of Compounds

Table S2 summarizes the means and standard deviations of $\lg K^m_{p,OM}$ and $\lg K^t_{p,OM}$ for selected *n*-alkanes and PAHs, and Figure 1 compares the mean $\lg K^m_{p,OM}$ and mean $\lg K^t_{p,OM}$ by species. Generally, the $p^{o,*}_L$ of *n*-alkanes predicted by the three methods and the corresponding $K^t_{p,OM}$ values were of the same order of magnitude

(Table 1, Table S2 in Supporting Information S1, and Figures 1a and 1c). When the SPARC method was applied to predict $p^{o,*}_L$, the scattering data of *n*-alkanes from Nanjing fell on the 1:1 line (Figure 1a), and those from Denver showed better agreement between $\lg K^{m}_{p,OM}$ and $\lg K^t_{p,OM}$. As shown in Table 1 and Table S2 in Supporting Information S1, the SPARC $p^{o,*}_L$ of the *n*-alkanes and the corresponding $K^t_{p,OM}$ are in best agreement with the literature $p^{o,*}_L$ and the derived $K^t_{p,OM}$. However, the mean $K^{m}_{p,OM}$ values of the Denver *n*-alkanes were 2–20 times higher than the mean $K^t_{p,OM}$. These results suggest that the gas-particle partitioning of *n*-alkanes in Nanjing can be explained primarily by equilibrium absorption into the OM phase in PM, whereas in Denver other sorption mechanisms (e.g., adsorption) should contribute to the partitioning of *n*-alkanes into the particle phase.

The $p^{o,*}_L$ values of the selected PAHs predicted by the TEST, SPARC, and SIMPOL methods varied by up to two orders of magnitude (Table 1). Only the scatter data based on SIMPOL estimation fell along a continuous line parallel to the identity line (Figures 1b and 1d). The comparisons of $p^{o,*}_L$ values from this study and from the literature (Table 1) also indicate that the SIMPOL $p^{o,*}_L$ of PAHs are the most reasonable estimates, and the mean $\lg K^t_{p,OM}$ of PAHs based on SIMPOL $p^{o,*}_L$ showed the best agreement with those based on literature $p^{o,*}_L$ (Table S2 in Supporting Information S1). Although the regression line of $\lg K^{m}_{p,OM}$ versus $\lg K^t_{p,OM}$ has a slope close to 1.0 for both Nanjing (0.94) and Denver (1.15), the intercept (0.50 and 1.25) suggests stronger sorption to the PM phase than absorptive partitioning. Several studies tended to fit the $\lg K^{m}_{p,OM}$ data of SVOCs in the same group by regression against their $\lg p^o_L$ (Liang et al., 1997; Liang & Pankow, 1996; Mader & Pankow, 2002), but a significant correlation and a slope close to unity do not necessarily indicate the dominance of the equilibrium absorptive partitioning according to Equation 2. In our previous studies, the $\lg K^{m}_{p,OM}$ of *n*-alkanes and PAHs were regressed on their $\lg K^t_{p,OM}$ to evaluate the simulation of gas-particle partitioning (Gou et al., 2021; Xie et al., 2014), but the effects of $p^{o,*}_L$ prediction were not considered, and the difference between $K^{m}_{p,OM}$ and K^t_p .

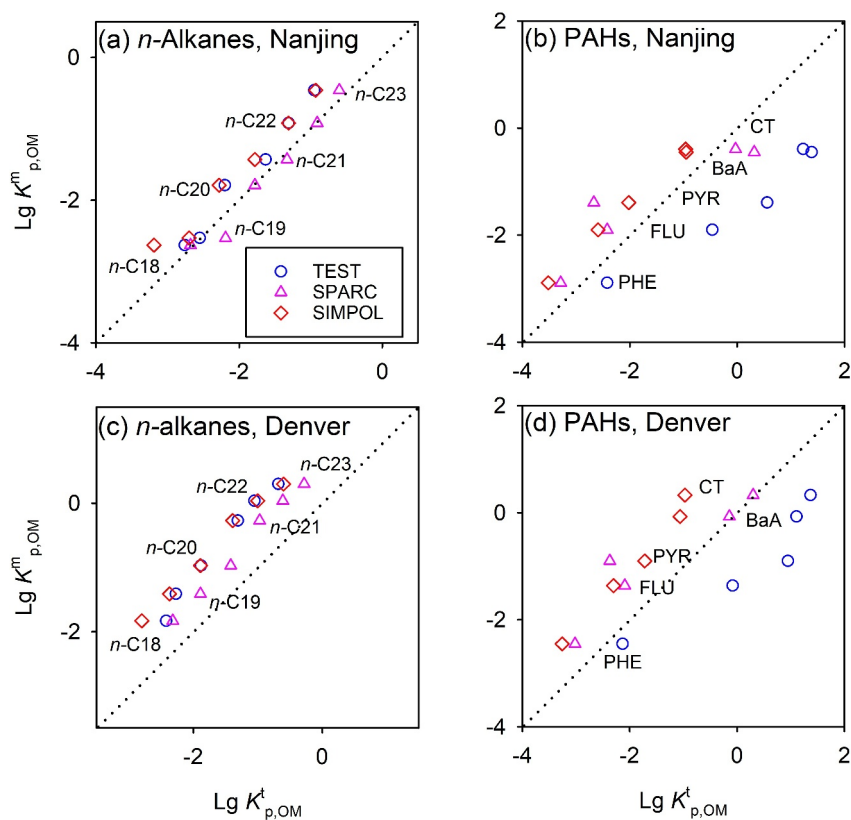

Figure 1. Comparisons of mean $\lg K^m_{p,OM}$ and mean $\lg K^t_{p,OM}$ for the selected *n*-alkanes and PAHs in panels (a, b) Nanjing and (c, d) Denver.

$K^m_{p,OM}$ can be up to two orders of magnitude. Even though the p^{0*}_L prediction method was selected here in advance to improve the simulation of $K^m_{p,OM}$, noticeable differences between $\lg K^m_{p,OM}$ and $\lg K^t_{p,OM}$ were still observed.

3.2. $\lg K^m_{p,PM2.5}$ Versus $\lg K^t_{p,PM2.5}$ Within Groups of Compounds

When both the absorption and adsorption mechanisms were involved for the prediction of the partitioning coefficient, the p^{0*}_L values of selected *n*-alkanes and PAHs were preferably estimated using the SPARC and SIMPOL methods, respectively, as they perform well in reproducing literature p^{0*}_L values and predicting $K_{p,OM}$. The means and standard deviations of $\lg K^m_{p,PM2.5}$ and $\lg K^t_{p,PM2.5}$ based on Nanjing and Denver data are shown in Table S3 in Supporting Information S1. Using SPARC p^{0*}_L and a Q_I-Q_v value of 0 kcal mol⁻¹, the mean $\lg K^m_{p,PM2.5}$ and $\lg K^t_{p,PM2.5}$ of the selected *n*-alkanes in Nanjing were almost identical (Table S3 in Supporting Information S1 and Figure 2a). However, in Denver, the Q_I-Q_v value needs to be increased to a value between 1.5 and 3.0 kcal mol⁻¹ to achieve a good match (Figure 2c). When p^{0*}_L was predicted by the TEST or SPARC method, the agreement between $\lg K^m_{p,PM2.5}$ and $\lg K^t_{p,PM2.5}$ cannot be obtained by assuming a single Q_I-Q_v value for all PAH species (Figures S1 and S2 in Supporting Information S1). In both Nanjing and Denver, the selected PAHs had greater Q_I-Q_v values than the *n*-alkanes (Figure 2). Table S4 in Supporting Information S1 provides the selection of Q_I-Q_v that best fit the mean $\lg K^m_{p,PM2.5}$ for *n*-alkanes and PAHs in Nanjing (0 and 2 kcal mol⁻¹) and Denver (2.6 and 3 kcal mol⁻¹) by retrieving the minimum average relative percent difference (ARPD, %). Thus, if the p^{0*}_L and Q_I-Q_v values are estimated appropriately, the inclusion of the adsorption mechanism can improve the simulation of gas-particle partitioning for the selected *n*-alkanes and PAHs.

A very small Q_I-Q_v value in the order of 0.25 kcal mol⁻¹ usually indicates liquid-like sorption (Pankow, 1987), and there is evidence that the complex mixtures of solid-like organic compounds in aerosols behave like a liquid (Cappa et al., 2008). However, the results shown here suggest that sorption is not liquid-like, especially for the

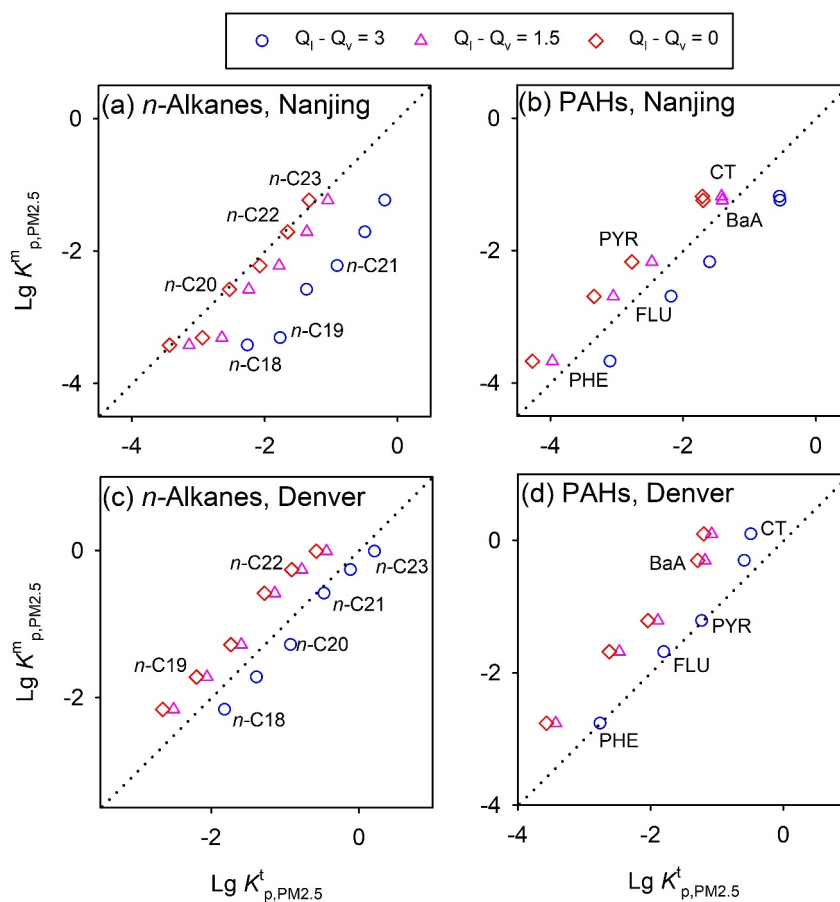

Figure 2. Comparisons of mean $\lg K^m_{p,PM2.5}$ and mean $\lg K^t_{p,PM2.5}$ for the selected *n*-alkanes and PAHs in panels (a, b) Nanjing and (c, d) Denver. The $p^{0,*}_L$ values of the selected *n*-alkanes and PAHs were predicted using the SPARC and SIMPOL methods, respectively.

target SVOCs in Denver. Compared to Nanjing, Denver has a much lower average humidity (Table 2), and ambient aerosols were expected to have low ALW content (Carlton & Turpin, 2013). Moreover, ambient air in Denver may contain more non-exchangeable *n*-alkanes and PAHs trapped in the PM or bound to highly active sites (Bidleman et al., 1986; Harner & Bidleman, 1998), resulting in a very slow equilibrium between the gas and particle phases. Despite the aerosol phase state is not completely clear, comparisons between Figures 1 and 2 show that physical adsorption plays an important role in the gas-particle partitioning. Based on the optimal selection of the $p^{0,*}_L$ estimation method and the $Q_l - Q_v$ values in Table S4 in Supporting Information S1, the adsorption mechanism contributes to 7.75% of the $K^t_{p,PM2.5}$ for the selected *n*-alkanes in Nanjing, supporting that the absorption mechanism dominates the gas-particle partitioning of *n*-alkanes in Nanjing. However, more than 70% of the $K^t_{p,PM2.5}$ for the selected PAHs in Nanjing and the target SVOCs in Denver were caused by the adsorption mechanism.

The dry mass of $PM_{2.5}$ is well reconstructed by inorganic ions, OC, and EC in Nanjing (Xie et al., 2022; Yu et al., 2020). In most air quality monitoring stations, hourly $PM_{2.5}$ concentrations were recorded at a relative humidity of <35% to minimize ALW content and avoid over-measuring. To understand whether dry $PM_{2.5}$ mass data can be used to parameterize the gas-particle partitioning of SVOCs in Nanjing, we proposed a partitioning between gas phase and reconstructed $PM_{2.5}$ ($rPM_{2.5}$) in Text S1 in Supporting Information S1. The concentration of $rPM_{2.5}$ was calculated as the sum of the measured inorganic ions, OM ($OC \times 1.6$), and EC (Table 2), and the mass fraction of OM in $rPM_{2.5}$ was used instead of f_{OM} to calculate $K^t_{p,rPM2.5}$. Table S5 in Supporting Information S1 lists the means and standard deviations of $\lg K^m_{p,rPM2.5}$ and $\lg K^t_{p,rPM2.5}$ based on the Nanjing data. Similar to the simulation of $K^m_{p,PM2.5}$, the agreement between $\lg K^m_{p,PM2.5}$ and $\lg K^t_{p,PM2.5}$ was satisfactory for all species when their $p^{0,*}_L$ estimation method and $Q_l - Q_v$ values were appropriately chosen (Figure S3 and Table

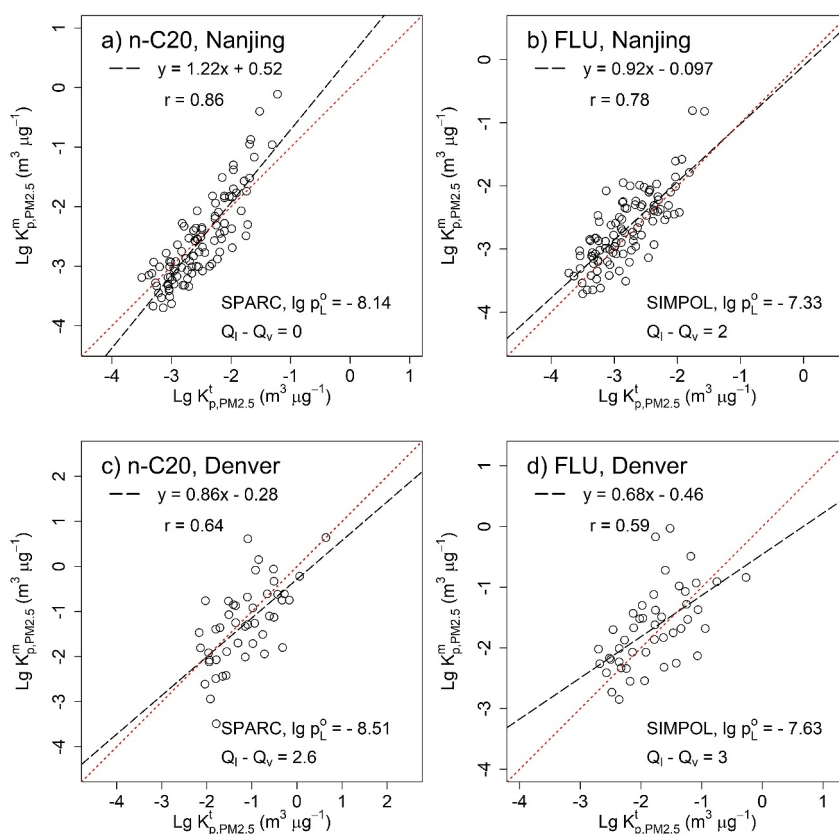

Figure 3. Comparisons of $\lg K^m_{p,PM2.5}$ and $\lg K^t_{p,PM2.5}$ for *n*-C20 and FLU in panels (a, b) Nanjing and (c, d) Denver. The selection of $p^{0,*}_L$ estimation method and $Q_l - Q_v$ values are shown in Table S4 in Supporting Information S1.

S4 in Supporting Information S1). Compared to sorption to $PM_{2.5}$, sorption of the selected PAHs to $rPM_{2.5}$ appears less liquid-like ($Q_l - Q_v = 2.4 \text{ kcal mol}^{-1}$; Table S4 in Supporting Information S1) possibly due to the exclusion of ALW.

3.3. $\lg K^m_{p,PM2.5}$ Versus $\lg K^t_{p,PM2.5}$ for Individual Compounds

Owing to the variations in ambient temperature (Table 2), the partitioning coefficient of the individual species can vary by several orders of magnitude within a year. To assess the simulation of temporal variations in partitioning coefficients, the $\lg K^m_{p,PM2.5}$ and $\lg K^t_{p,PM2.5}$ of *n*-C20 and FLU in Nanjing and Denver are compared for all samples in Figure 3, and the comparisons for other species are shown in Figures S4 and S5 in Supporting Information S1. For the calculation of $K^t_{p,PM2.5}$, the selection of $p^{0,*}_L$ estimation methods and $Q_l - Q_v$ values given in Table S4 in Supporting Information S1 were used. The scattering data of most species in Nanjing followed a continuous line, and all regression slopes of PAHs are close to 1.0 (0.92–1.05). However, for *n*-alkanes with carbon number >20, the regression slopes were well above 1.0 (Figures S4c–S4e in Supporting Information S1), which was attributed to deviations from true equilibrium sorption, measurement artifacts, or changes in sorbent properties (Goss & Schwarzenbach, 1998; Pankow & Bidleman, 1992).

In this work, the gas-particle partitioning of selected *n*-alkanes and PAHs was predicted based on established absorptive and adsorptive mechanisms without considering the phase state of the particles, which can change with aerosol composition and meteorological conditions (e.g., temperature and humidity; Shiraiwa et al., 2017; Liu et al., 2019). Once the aerosol phase state changes from a liquid to a semisolid or glassy state, the partitioning of SVOCs can be kinetically inhibited, resulting in longer equilibration time scales or even non-equilibrium partitioning (Koop et al., 2011; Shiraiwa et al., 2013; Virtanen et al., 2010; Zobrist et al., 2008). Given the dependence of aerosol phase state on temperature (Petters et al., 2019; Slade et al., 2017) and the limited number

of sample pairs in this work, the comparisons of $\lg K_{p,PM2.5}^m$ and $\lg K_{p,PM2.5}^l$ of *n*-C20 and FLU are divided into two groups by temperature in Figure S6 in Supporting Information S1. It can be seen that the regression slopes show a larger deviation from unity in lower temperature ranges, which may be partly ascribed to the change of aerosol phase state with temperature. In addition, integrated sampling was conducted in Nanjing and Denver for 12 and 24 hr, respectively, when the ambient temperature and atmospheric concentrations fluctuated. In this case, the target compounds could condense or evaporate on the particles originally collected on the filter during each sampling interval. Therefore, the *F* and *A* values of each pair of samples can hardly reflect the averaged instantaneous concentrations of SVOCs in the particulate and gas phases. Gou et al. (2021) found that the regression slopes of $\lg K_{p,OM}^m$ and $\lg K_{p,OM}^l$ depend on how the sampling artifact was adjusted based on Q_b measurements. Here, we roughly divided the Q_b concentrations equally into positive and negative artifacts, which could also be a possible reason for the deviation of the regression slopes from 1.0. But unfortunately, it is not possible to obtain unbiased *F* and *A* values with the current sampling method. For future studies, highly time-resolved measurements are required to reduce the effects of variations in temperature and atmospheric concentrations during sampling, and the effects of changes in the phase state of atmospheric aerosols on the partitioning of SVOCs need to be quantitatively evaluated.

As shown in Figures 3c and 3d and Figure S5 in Supporting Information S1, the comparisons of $\lg K_{p,PM2.5}^m$ and $\lg K_{p,PM2.5}^l$ for the target compounds are more scattered in Denver than in Nanjing, although the data for most species are almost evenly distributed on the two sides of the identity line. Because Denver has a longer cold period and lower temperatures than Nanjing, and the average concentrations of the low-volatility *n*-alkanes and PAHs were also much lower in Denver than in Nanjing (Table 2), the gas-phase concentrations of the heavier *n*-alkanes and PAHs in Denver were subject to greater uncertainties. Mader and Pankow (2002) found that normalization of K_p values by f_{OM} can reduce the degree of variation in the partitioning data ($\lg K_{p,OM}^m$ vs. $\lg p_L^m$). This phenomenon was also observed in Denver in the comparisons of $\lg K_{p,OM}^m$ and $\lg K_{p,OM}^l$ (Figure S7 in Supporting Information S1), but not in Nanjing (Figure S8 in Supporting Information S1). It is therefore suspected that the adsorption-dominated $K_{p,PM2.5}^m$ in Denver is more influenced by the change in aerosol phase state and biased *F* and *A* during integrated sampling than in Nanjing.

4. Conclusions

The comparison results of $\lg K_{p,OM}^m$ and $\lg K_{p,OM}^l$ show that the gas-particle partitioning of semi-volatile *n*-alkanes in Nanjing can be predicted quite well by the equilibrium absorptive partitioning theory, which, however, cannot fully explain the sorption of *n*-alkanes in Denver. Even if the estimation method of $p_L^{o,*}$ was preselected to improve the agreement between $\lg K_{p,OM}^m$ and $\lg K_{p,OM}^l$, PAHs exhibited stronger sorption to $PM_{2.5}$ than the prediction based on OM absorption. Good agreement between $\lg K_{p,PM2.5}^m$ and $\lg K_{p,PM2.5}^l$ can be obtained by selecting the $p_L^{o,*}$ estimation method and the Q_l-Q_v value for both the Nanjing and Denver data. Unlike *n*-alkanes in Nanjing, the adsorption mechanism in Denver dominates the gas-particle partitioning of all selected SVOCs, and the sorption is less liquid-like, which may be due to the low ALW content. Besides the mean values of $\lg K_{p,PM2.5}^m$ within groups of compounds, temporal variations were also adequately reflected by $\lg K_{p,PM2.5}^l$. Thus, the prediction of the gas-particle partitioning behavior of non-polar SVOCs considering absorption and adsorption mechanisms is promising. Since the variations in aerosol phase state, ambient temperature, and atmospheric concentrations during integrated sampling are responsible for the difference between measured and predicted partitioning coefficients, more efforts (e.g., highly time-resolved measurements) are needed to address these issues in future studies.

Conflict of Interest
