Abstract. A global three-dimensional model of tropospheric chemistry is used to investigate the changes in tropospheric \( \text{O}_3 \) and OH since preindustrial times as a result of fuel combustion and industry, biomass burning, and growth in atmospheric \( \text{CH}_4 \). Model results indicate a 63\% increase of the global tropospheric \( \text{O}_3 \) burden from preindustrial times to present (80\% and 50\% in the northern and southern hemispheres, respectively). Anthropogenic emissions of \( \text{NO}_x \) and of CO and hydrocarbons make comparable contributions to the global \( \text{O}_3 \) increase (60\% and 40\% respectively), even though the local rate of tropospheric \( \text{O}_3 \) production is generally \( \text{NO}_x \) limited. The rise in \( \text{O}_3 \) production parallels closely the rise in the emissions of CO and hydrocarbon because the \( \text{O}_3 \) yield per mole of CO or hydrocarbon oxidized has remained constant at 0.7-0.8 mol/mol since preindustrial times. In contrast, the \( \text{O}_3 \) production efficiency per mole of \( \text{NO}_x \) emitted has decreased globally by a factor of 2. We find a 9\% decrease in the global mean OH concentration (mass-weighted) since preindustrial times. A linear relationship is found in the model between the global mean OH concentration and the \( S_N/S_C^{3/2} \) ratio, where \( S_N \) and \( S_C \) are the sources of \( \text{NO}_x \) and of CO and hydrocarbons, respectively. The relative constancy of the global mean OH concentration since preindustrial times reflects the conservation of the \( S_N/S_C^{3/2} \) ratio despite large increases in both \( S_N \) and \( S_C \). Comparisons of model results with reconstructed nineteenth century observations of \( \text{O}_3 \) at continental sites indicate a systematic overestimate of about 5 ppbv. Correcting this overestimate would require either a large missing chemical sink for \( \text{O}_3 \) or a downward revision of the natural \( \text{NO}_x \) source from lightning (3 Tg N yr\(^{-1}\) in our model). The nineteenth century observations of \( \text{O}_3 \) over Europe show no vertical gradient between the boundary layer and the free troposphere, which is inconsistent with our current understanding of tropospheric \( \text{O}_3 \). The model underestimates preindustrial CO concentrations derived from polar ice cores; these measurements are difficult to reconcile with any reasonable CO emission inventories.

1. Introduction

Preindustrial measurements of \( \text{O}_3 \) concentrations at surface sites in western Europe and South America indicate an increase of several fold from preindustrial times to present [Volz and Kley, 1988; Anfossi et al., 1991; Sandroni et al., 1992; Marenco et al., 1994]. This increase is likely driven by anthropogenic emissions of \( \text{NO}_x \) (\( \text{NO} + \text{NO}_2 \)), CO, and hydrocarbons from fossil fuel combustion and biomass burning. Increasing concentrations of \( \text{O}_3 \), \( \text{NO}_x \), CO, and hydrocarbons may have also induced significant changes in the abundance of tropospheric OH, the main atmospheric oxidant [Thompson, 1992]. Since tropospheric \( \text{O}_3 \) is a greenhouse gas and OH concentrations determine the lifetimes of greenhouse gases such as \( \text{CH}_4 \) and hydrochlorofluorocarbons (HCFCs), anthropogenic perturbations to tropospheric \( \text{O}_3 \) and OH have important implications for climate change [Intergovernmental Panel on Climate Change (IPCC), 1996].

A number of model studies have attempted to describe the changes of tropospheric \( \text{O}_3 \) and OH concentrations since preindustrial times: one-dimensional models before the early 1990s [Thompson, 1992] and two- and three-dimensional models more recently [Crutzen and Zimmermann, 1991; Thompson et al., 1993; Martinet et al., 1995; Lelieveld and Van Dorland, 1995; Kasibhatla et al., 1996; Levy et al., 1997; Roelofs et al., 1997; Berntsen et al., 1997]. Three-dimensional model simulations suggest an increase in global \( \text{O}_3 \) concentrations since preindustrial times ranging from 40\% [Levy et al., 1997; Roelofs et al., 1997] to 70\% [Lelieveld and Van Dorland, 1995]. The estimated change of the global mean OH concentration ranges from a 20\% decrease [Thompson et al., 1993] to a 6-7\% increase [Martinerie et al., 1995; Berntsen et al., 1997]. The relatively small OH changes in these models reflect compensating anthropogenic influences from large increases in \( \text{NO}_x \) and \( \text{O}_3 \) which tend to enhance OH, and large decreases in CO and hydrocarbons, which tend to decrease OH [Thompson, 1992].

We use in this work a global three-dimensional model of tropospheric \( \text{O}_3 \)-\( \text{NO}_x \)-hydrocarbon chemistry [Wang et al., 1998a, b, c] to better understand how anthropogenic emissions
have driven changes in O₃ and OH concentrations since preindustrial times. A brief description of the model is given in section 2, and results for the preindustrial and present atmospheres are presented in section 3. The model has been evaluated previously with observations for the present atmosphere [Wang et al., 1998b], and we extend in section 4 this evaluation to reconstructed observations of O₃, CO, and OH proxies from the nineteenth century. In section 5, we interpret changes in O₃ and OH concentrations over the past century on the basis of changing anthropogenic emissions. Conclusions are in section 6.

2. Model Description

Our global three-dimensional model for tropospheric O₃, NOₓ, hydrocarbon chemistry is described by Wang et al. [1998a]. The model is driven by meteorological fields archived every 4 hours from a general circulation model developed at the Goddard Institute for Space Studies [Hansen et al., 1983]. It has a spatial resolution of 4° latitude by 5° longitude with seven vertical layers extending from the surface to 150 mbar. The model transports 15 chemical tracers: odd oxygen (O₃ + O + NO₂ + HNO₃ + 2 × NO₃ + 3 × N₂O₅), NOX (NO + NO₂ + NOₓ + HNO₃), N₂O₅, HNO₃, HNO₄, peroxyacetyl nitrates, alkyl nitrates, CO, Cthc, C₅-C₆ alkenes, C₆-C₁₀ alkenes, isoprene, acetone, higher ketones, and H₂O₂. Spatially and seasonally varying flux boundary conditions are specified at 150 mbar to represent the cross-tropopause transport of O₃ (400 Tg O₃ yr⁻¹) and of total reactive nitrogen NOₓ (0.48 Tg N yr⁻¹). The present-day simulation includes anthropogenic sources from fuel combustion and industry (22 Tg N yr⁻¹ of NOₓ, 520 Tg CO yr⁻¹, and 56 Tg C yr⁻¹ of nonmethane hydrocarbons (NMHCs)), biomass burning (12 Tg N yr⁻¹ of NOₓ, 520 Tg CO yr⁻¹, and 51 Tg C yr⁻¹ of NMHCs), and soil emission of NOₓ associated with fertilizer usage (1.3 Tg N yr⁻¹). Natural emissions are from lightning (3.0 Tg N yr⁻¹ of NOₓ), soils (4.7 Tg N yr⁻¹ of NOₓ), and vegetation (600 Tg C yr⁻¹ of isoprene and 15 Tg C yr⁻¹ of acetone). Dry deposition is computed with a resistance-in-series scheme.

The model simulation for the present atmosphere has been evaluated extensively by Wang et al. [1998b] with long term measurements of O₃ (surface sites and ozonesondes) and CO (surface sites) and with aircraft measurements of NO, peroxyacetyl nitrate (PAN), HNO₃, C₃H₆, acetone, and H₂O₂ in different regions of the troposphere. The model reproduces observed monthly mean concentrations of O₃ generally to within 10 ppbv and captures the observed seasonal variations of O₃ to within 1 month. Ozone concentrations tend to be overestimated in the tropical marine boundary layer and underestimated in the upper troposphere of the southern tropics. Observed concentrations of NO and PAN are reproduced generally to within a factor of 2; HNO₃ concentrations tend to be overestimated, sometimes several fold. Concentrations of CO are reproduced to generally within 10 ppbv and concentrations of H₂O₂ are reproduced to within a factor of 2. The global mean OH concentration simulated in the model yields a lifetime of 5.1 years for CH₃CCl₃ below 200 mbar against oxidation by OH, in agreement with the estimate of 4.9±0.3 years derived from long-term observations of CH₃CCl₃ by Prinn et al. [1995].

We simulate the preindustrial atmosphere (circa 1850) by removing anthropogenic emissions from the present-day simu-

| Table 1. Global Sources of NOₓ, CO and Hydrocarbons, and Global Mean OH Concentrations |
|---------------------------------------------|---------------|---------------|---------------|---------------|---------------|
| Preindustrial² | A 1.7 ppmv CH₄ | B Present CO + NMHCs | C Present NOₓ | D Present Fuel + Industry | E Present Biomass Burning |
| NOₓ (Sₓ) | 0.64 | 0.64 | 0.64 | 2.9 | 2.1 | 1.4 | 3.0 |
| CO and Hydrocarbons | | | | | | | |
| CO² | 24 | 34 | 58 | 29 | 45 | 43 | 76 |
| CH₄² | 14 | 24 | 10 | 20 | 15 | 15 | 29 |
| Nonmethane hydrocarbons (NMHCs) | | | | | | | |
| Total (Sₓ) | 48 | 68 | 81 | 59 | 72 | 69 | 118 |
| Global mean OH² | 1.15 | 0.95 | 0.78 | 1.56 | 1.18 | 1.19 | 1.04 |

Sources of NOₓ and of CO and hydrocarbons are in Tmol yr⁻¹; global mean OH concentrations are in 10⁶ molecules cm⁻³.

²Preindustrial emissions include NOₓ from lightning, unfertilized soils, and 10% of present-day biomass burning, isoprene and acetone from terrestrial vegetation, and CO and NMHCs from 10% of present-day biomass burning. Methane concentration is specified at 0.8 ppmv.

²The sensitivity cases include A, preindustrial atmosphere with present-day CH₄ concentration of 1.7 ppmv; B, preindustrial atmosphere with present-day emissions of CO and NMHCs from fuel combustion, industry, and biomass burning; C, preindustrial atmosphere with present-day NOₓ emissions from fossil fuel combustion and biomass burning (but not including soil emissions from fertilizer use of 0.1 Tmol yr⁻¹); D, preindustrial atmosphere with present-day NOₓ, CO and NMHC emissions from fuel combustion and industry; E, preindustrial atmosphere with present-day biomass burning emissions of NOₓ, CO, and NMHCs.

²Wang et al. [1998a].

²Including direct CO emission and CO production from hydrocarbon oxidation.

²Source needed to sustain the specified concentration of CH₄ (0.8 ppmv in the preindustrial simulation and sensitivity simulations B-E, 1.7 ppmv in sensitivity simulation A and the present-day simulation).

²Weighted by atmospheric mass in the column up to 150 mbar.
lation (Table 1). Natural emissions (vegetation, soils, and lighting) and cross-tropopause fluxes of O$_3$ and NO$_x$ are assumed to be the same as in the present atmosphere. We exclude emissions from fossil fuel combustion and industry: Dignon and Hameed [1989] estimated a global NO$_x$ source from fossil fuel combustion of 0.4 Tg N yr$^{-1}$ in 1860, as compared to 22 Tg N yr$^{-1}$ in 1980. We also exclude soil NO$_x$ emission from fertilizer use. The concentration of CH$_4$ is specified at 0.8 ppmv on the basis of ice core data, as compared to 1.7 ppmv for the present atmosphere [IPCC, 1996]. Changes since preindustrial times in land use, meteorology, aerosols, and stratospheric O$_3$ columns are not considered.

Historical trends in biomass burning are uncertain. The Greenland ice core record of ammonia does not show a systematic trend over the past 150 years [Fuhrer et al., 1996] implying a relative constant fire activity at high northern latitudes. However, biomass burning takes place principally in the tropics. As will be discussed in section 4, nineteenth century observations of O$_3$ in South America [Sardroni et al., 1992] imply a much weaker tropical biomass burning source than that of today. Following Crutzen and Zimmermann [1991], we assume in our standard simulation that preindustrial biomass burning emissions are 10% of the present day value and retain the same geographic distribution. We also conduct a sensitivity simulation assuming a preindustrial biomass burning source the same as that of today.

Nitrate records in polar ice cores offer some indication of trends in combustion since preindustrial times, but caution is necessary in interpreting these records owing to possible HNO$_3$ evaporation from snow and firm [Dibb et al., 1998]. The Greenland observations show a factor of 3 increase in nitrate deposition since preindustrial times [Mayewski et al., 1990], while our model results for Greenland give a factor of 6 increase. The Antarctic observations show large interannual variability in nitrate over the past century but no systematic trend [Mayewski and Legrand, 1990]. Our model indicates an increase of 50% in nitrate deposition over Antarctica owing to long-range transport of biomass burning emissions; such a trend could have been masked in the observations by the high interannual variability.

3. Ozone and OH: Preindustrial Versus Present Atmosphere

Simulated mean concentrations of O$_3$ and CO near the surface in July are shown in Figure 1 for the preindustrial and
Figure 2a. Zonally averaged annual mean concentrations of $O_3$ (ppbv), $OH$ ($10^5$ molecules cm$^{-3}$), $NO_x$ (pptv), and $CO$ (ppbv) as a function of pressure and latitude for the preindustrial and present atmospheres.

Preindustrial $O_3$ concentrations in the northern hemisphere are about 10-15 ppbv and are lower than in the southern hemisphere (15-20 ppbv) because of the larger amount of $O_3$ transported from the stratosphere in the winter hemisphere and the enhanced chemical loss of $O_3$ in the summer hemisphere. In contrast, present-day $O_3$ concentrations in the northern hemisphere (20-50 ppbv) are a factor of 2 to 4 higher than in preindustrial times and are also higher than in
the present southern hemisphere (20-40 ppbv) owing to enhanced summertime photochemical production associated with emissions from fuel combustion and industry. Simulated CO concentrations are a factor of 2 to 5 lower in preindustrial times than at present owing to lower preindustrial concentrations of CH₄ and lower direct emissions of CO. Higher CO concentrations over the continents of the northern hemisphere in preindustrial times are due to CO production from the oxidation of isoprene.

Zonally averaged annual mean concentrations of O₃, OH, NOₓ, and CO simulated for preindustrial and present atmospheres are shown in Figure 2a; relative changes from preindustrial times to present are shown in Figure 2b. Simulated O₃ concentrations for the preindustrial atmosphere show a much smaller interhemispheric asymmetry than at present. Somewhat higher O₃ concentrations in the northern than in the southern hemisphere in preindustrial times are due mostly to a larger stratospheric source in the northern hemisphere and a larger source of NOₓ from soils. Model results indicate that mean tropospheric O₃ concentrations have increased since preindustrial times by 80% in the northern hemisphere and by 50% in the southern hemisphere. Concentrations in the upper troposphere, where O₃ is an effective greenhouse gas, have increased by 20-80%. This increase is largest in the tropics where O₃ transport from the stratosphere is negligible [Holton et al., 1995].

We find that the global tropospheric O₃ burden (integrated from the surface up to 150 mbar) has increased by 63% from 4.0 x 10¹² mol in preindustrial times to 6.5 x 10¹² mol today. This increase is similar to the estimate of 70% by Lelieveld and Van Dorland [1995], but is higher than the estimates of 40% by Levy et al. [1997] and Roelofs et al. [1997]. The lower estimate by Levy et al. [1997] is likely due to their assumption of present-day CH₄ and CO concentrations for the preindustrial atmosphere; in our preindustrial simulation, increasing the concentration of CH₄ from 0.8 to 1.7 ppmv alone increases the global O₃ burden by 13%. The lower estimate by Roelofs et al. [1997] is due in part to a 40% decrease in the cross-tropopause O₃ flux from preindustrial times to present in their simulation. Some difference among the models is also expected from adoption of different tropopause levels for budget analysis.

Table 2 shows our global budgets of tropospheric O₃ for the preindustrial and present-day simulations. Our budget for the present atmosphere is discussed by Wang et al. [1998b, c] and is consistent with results from other recent three-dimensional models. Our estimate for chemical production of O₃ in the preindustrial troposphere is almost identical to the estimates by Crutzen [1994] and Roelofs et al. [1997], while our estimate for chemical loss of O₃ is 10% higher than Crutzen [1994] and 14% lower than Roelofs et al. [1997]. The lower estimate of chemical loss by Crutzen [1994] is due to a 40% higher O₃ loss to dry deposition than in our model; the higher estimate by Roelofs et al. [1997] is due to a 30% lower loss to dry deposition and a 50% higher cross-tropopause flux than in our model.

We find that the budget of tropospheric O₃ is dominated by chemical production and loss within the troposphere for both the present and preindustrial atmospheres. The globally averaged lifetime of O₃ has decreased by 20% since preindustrial times because most of the increase of O₃ concentrations has been in the lower troposphere (Figure 2b) where the lifetime of O₃ is shorter than in the middle and upper troposphere [Wang et al., 1998c]. As a result, although chemical production of O₃ at present is more than twice that in preindustrial times, the O₃ burden in the troposphere is only 63% higher.

The budgets and production efficiencies are for odd oxygen (O\(_2\) = O + NO + NO\(_2\) + HNO\(_4\) + 2 x NO\(_2\) + 3 x N\(_2\)O\(_5\) + organic nitrates + HNO\(_3\)) in the model air column from the surface to 130 mbar (specified as the tropopause). Over 95% of O\(_3\) is O\(_3\). Chemical production of O\(_3\) is by reactions of peroxy radicals with NO\(_x\) and chemical loss is principally through the reactions O\(_1\)D+H\(_2\)O, O\(_3\)+HO\(_2\), and O\(_3\)+OH. Sensitivity cases are the same as in Table 1.

Our model results for OH indicate that concentrations have either increased or decreased since preindustrial times depending on the region (Figure 2b). This variability reflects largely the regional variability in the enhancements of NO\(_x\) and O\(_3\), which tend to increase OH. Enhancements of CO and CH\(_4\), which tend to decrease OH, are much more uniform in the troposphere. In the lower troposphere of the northern hemisphere, where NO\(_x\) and O\(_3\) are strongly enhanced, OH concentrations show a 20-60% increase. In the middle and upper troposphere where NO\(_x\) and O\(_3\) enhancements are modest, OH concentrations show a 20% decrease.

Preindustrial OH concentrations are almost symmetric across the equator, while present-day OH concentrations are higher in the northern than in the southern hemisphere. The impact of anthropogenic emissions on OH concentrations is asymmetric because the lifetimes of CO (a few months) and CH\(_4\) (about 10 years) are much longer than that of NO\(_x\) (hours to days) allowing CO and CH\(_4\) but not NO\(_x\) to be transported to the southern hemisphere from the northern hemisphere where 90% of the fossil fuel combustion source and most of CH\(_4\) sources are located. The interhemispheric asymmetry in the change of OH concentrations was previously simulated by Crutzen and Zimmermann [1991]; the increase of OH concentrations in the lower troposphere of the northern hemisphere is larger and broader in our model than in theirs.

We find that the mass-weighted global mean OH concentration below 150 mbar has decreased by 9% from 1.15 x 10\(^{6}\) molecules cm\(^{-3}\) (preindustrial) to 1.04 x 10\(^{6}\) molecules cm\(^{-3}\) (present). However, the lifetime of CH\(_2\)CCl\(_3\) against OH oxidation has remained at 5.1 years; the increase of OH concentrations in the lower troposphere, where the rate constant for CH\(_2\)CCl\(_3\) oxidation is higher owing to warmer temperatures, has compensated for a lower precent-day global mean OH concentration. Previous model calculations of the trend in the mass-weighted global mean OH concentration from preindustrial times to present indicated a 6-7% increase [Martinovic et al., 1995; Bernsten et al., 1997], a 3% decrease [Lelieveld and Van Dorland, 1995], a 10-15% decrease [Crutzen and Zimmermann, 1991], and a 22% decrease [Roelofs et al., 1997]. Earlier estimates based largely on one-dimensional models indicated a 10-30% decrease [Thompson, 1992]. The general consensus among the current generation of models is that the global mean OH concentration has remained to within 20% of the present-day value since preindustrial times.

### 4. Model Evaluation With Preindustrial Observations

#### 4.1. Ozone

Nineteenth century concentrations of O\(_3\) at a number of continental sites have been reconstructed from old measurements made with impregnated papers and a colorimetric scale. A detailed review is given by Marenco et al. [1994]. According to this review, some early reconstructions including by Linville et al. [1980] (15-50 ppbv in Michigan), Bojkov [1986] (15-26 ppbv at sites in North America and Europe), and Lissac and Grubisich [1991] (30-36 ppbv in Yugoslavia) have positive biases due to incorrect calibrations. For comparison with our model results, we use the reconstructed data by Anfossi et al. [1991] and Marenco et al. [1994] for France and Italy and those by Sandroni et al. [1991] for Argentina and Uruguay. These reconstructions used similar calibrations [Marenco et al., 1994].
Figure 3. Simulations and reconstructed observations of preindustrial \( \text{O}_3 \) concentrations (ppbv) in surface air over Europe and South America: Montsouris, France (1876-1886) [Anfossi et al., 1991], Pic du Midi, France (1874-1881, the Plantade Station, Elevation 2.4 km) [Marenco et al., 1994], Moncalieri, Italy (1868-1893) [Anfossi et al., 1991], Cordoba, Argentina (1886-1892) [Sandroni et al., 1992], and Montevideo, Uruguay (1883-1885) [Sandroni et al., 1992]. Reconstructed observations are open circles; results from the standard preindustrial simulation (with biomass burning source reduced to 10% of the present-day value) are solid lines, results from a preindustrial simulation without the \( \text{O}_3 \) source from the stratosphere are dotted lines; and results from a preindustrial simulation with the present-day biomass burning source (\( \text{NO}_x \), CO, and NMHCs) are dashed lines.

Figure 3 compares the reconstructed observations with model simulations of surface \( \text{O}_3 \) concentrations for the preindustrial atmosphere. The reconstructed data generally show \( \text{O}_3 \) concentrations of 7-12 ppbv. The weak winter-spring maximum in the European observations is reproduced by the model, where it reflects the stratospheric influence (Figure 3). Observations from South America show no significant springtime enhancement from biomass burning, in contrast to the present atmosphere [Kirchoff and Rasmussen, 1990], implying a much weaker biomass burning source in preindustrial times than that of today. Including the present-day biomass burning source in our standard preindustrial simulation leads to a 10-20 ppbv increase of \( \text{O}_3 \) concentrations in northern Argentina and Uruguay during the austral burning season of August-November (Figure 3).

Figure 3 shows that our standard preindustrial simulation overestimates the reconstructed observations consistently by 0-20 ppbv. The discrepancies are particularly large in the winter season of both hemispheres, reflecting a greater seasonal amplitude in the model (driven by the stratospheric influence). The preindustrial observations in Figure 3 were typically taken around the clock, and some of the model overestimate may be due to nighttime \( \text{O}_3 \) depletion by dry deposition in a shallow stable surface layer sampled by the observations but not resolved by the model [Jacob et al., 1993]. Negative interference to \( \text{O}_3 \) measurements by \( \text{NH}_3 \) or \( \text{SO}_2 \) could also contribute [Anfossi and Sandroni, 1997]. Loss of \( \text{O}_3 \) to natural organic aerosols or to a denser preindustrial vegetation canopy could further mitigate some of the overestimates in summer. These effects are, however, unlikely to explain the seasonal pattern of the overestimates and should not be an issue at Pic du Midi, a mountain site [Marenco et al., 1994]. Model results from a sensitivity simulation in which \( \text{O}_3 \) transport from the stratosphere is excluded are in much better agreement with the reconstructed observations (Figure 3). However, there is no physical basis to suspect that \( \text{O}_3 \) transport from the stratosphere to the troposphere in preindustrial times was much less or had a different seasonal variation from present [Holton et al., 1995].

Previous global three-dimensional model simulations of the preindustrial atmosphere show similar tendencies to overestimate \( \text{O}_3 \) concentrations. Roelofs et al. [1997] find mean surface \( \text{O}_3 \) concentrations over Europe of 10-15 ppbv in summer and 15-20 ppbv in winter, in good agreement with ours, while Levy et al. [1997] find corresponding values of 7-9 ppbv in summer and 20 ppbv in winter (H. Levy II., personal communication, 1997). The best simulation would appear to be that of Bermsen et al. [1997] which yields surface \( \text{O}_3 \) concentrations of 10 ppbv at Paris with little seasonal variation. However, that simulation assumes excessive \( \text{O}_3 \) deposition velocities: 0.5 cm s\(^{-1}\) in summer and 0.4 cm s\(^{-1}\) in winter over Europe referenced to 200 m altitude (lowest model layer) [Bermsen and Isaksen, 1997]. These values are about a factor of 2 too high when compared to resistance-in-series models which account for the
31,130 WANG AND JACOB. ANTHROPOGENIC FORCING ON TROPOSPHERIC O3 AND OII

![Graph showing CO concentrations over Greenland and Antarctica over different months.]

**Figure 4.** Measured and simulated preindustrial CO concentrations (ppbv) over Greenland and Antarctica. Ice core measurements by Haaø et al. [1996] (annual averages) represented in solid lines are for the periods of 1802-1862 (Greenland) and 1860-1916 (Antarctica). Dotted lines are results from the standard preindustrial simulation with the biomass burning source reduced to 10% of the present-day value, and dashed lines are results from a preindustrial simulation with the present day biomass burning source (NOx, CO, and NMHCs).

The effect of nighttime stability in the 0-200 m column and a lack of stomatal uptake of O3 in winter [Jacob et al., 1993; Gunzeveld and Lieblieveld, 1995; Munger et al., 1998; Wang et al., 1998a].

The most troubling discrepancy in Figure 3 is at Pic du Midi (2.4 km altitude), where the preindustrial data should not be affected by chemical interferences from NH3 or SO2 and where local surface effects should be minimal [Marenco et al., 1994]. Matching the nineteenth century Pic du Midi observations in our model, assuming the same stratospheric source as that of today and some natural NOx emissions (lightning and soils), would require a large missing chemical sink of O3 in the troposphere. A perplexing aspect of the Pic du Midi preindustrial observations is the lack of vertical gradient relative to Montsouris (Figure 3). Present-day vertical profiles of O3 concentrations at remote continental sites typically show differences of 10-20 ppbv between the sea level and 2-3 km altitude as a result of chemical loss and dry deposition in the boundary layer [Anderson et al., 1994; Mauzerall et al., 1996]. Anfossi et al. [1991] found in the nineteenth century Moncalieri data that O3 concentrations associated with downslope winds from the Alps (föhn) were 5-10 ppbv higher than average, suggesting an increase of O3 concentrations with altitude which is at odds with the Pic du Midi data.

### 4.2. Carbon Monoxide

A recent analysis of ice core CO records shows concentrations of 91 ppbv in central Greenland for the period of 1802-1862 and 57 ppbv in Antarctica for the period of 1860-1916 [Haaø et al., 1996]. Figure 4 compares these data with model results for Greenland and Antarctica. The standard model for the preindustrial atmosphere is too low by a factor of 4 and does not show the observed interhemispheric asymmetry. When the present-day biomass burning source is included, model results are still a factor of 2 too low and exhibit little interhemispheric asymmetry. As discussed in section 4.1, the reconstructed O3 observations in South America imply a biomass burning source in the nineteenth century much less than that of today.

Previous model simulations for the preindustrial atmosphere, reviewed by Haaø et al. [1996], also underestimate the ice core data. Haaø et al. [1996] suggested that the underestimate could reflect the neglect of nineteenth century industrial emissions in the models. However, these emissions would have to be unrealistically large. As Haaø et al. [1996] noted, the ice core record for 1860-1916 over Antarctica indicates CO concentrations similar to those observed today. The background CO concentration from CH4 oxidation, however, has increased by 15 to 20 ppbv since preindustrial times. The ice core data for 1802-1862 over Greenland are not much lower than an annual mean concentration of 115 ppbv simulated in our model for the present atmosphere. The ice core data of Haaø et al. [1996] would thus imply higher CO and NMHC emissions in the nineteenth century than at present in the southern hemisphere and comparable emissions in the northern hemisphere. Such a scenario is inconsistent with historical trends in fossil fuel combustion and is also inconsistent with the observed increase in tropospheric CO over Jungfraujoch (Switzerland) from 1950 to present [Zander et al., 1989]. The Jungfraujoch measurements for 1950-1951 indicate 67 ppbv CO, which is lower than the Greenland ice core concentration of 91 ppbv reported by Haaø et al. [1996] for the nineteenth century.

### 4.3. Hydrogen Oxide Radicals

Trends in the concentrations of hydrogen oxide radicals (HOx=OH+HO2) since preindustrial times have been estimated by Stuffle et al. [1991] and Anklín and Roles [1997] using CH3O and H2O2 records from Greenland ice cores. Interpretation of these records is subject to caution.
because of possible post-depositional exchange with the atmosphere, reactions within the ice, and secular changes in the seasonal accumulation of snow [Nefel et al., 1995]. The record of CH$_4$ suggests a 30% decrease in OH concentrations since preindustrial times [Staffelbach et al., 1991]; our corresponding model results over Greenland show a 12% decrease. Data for H$_2$O$_2$ in Greenland ice cores show constant concentrations from preindustrial times until about 1970 and a doubling of concentrations since then which would suggest a rise in NO$_2$ concentrations [Sigg and Nefel, 1991; Anklin and Bales, 1997]. Our model shows a factor of 2.5 increase of H$_2$O$_2$ concentrations over Greenland from preindustrial times to today because of the increasing source of NO$_2$ radicals as tropospheric O$_3$ concentrations increase.

5. Ozone and OH: Relationship to Anthropogenic Emissions

The major forcings of O$_3$ and OH concentrations since preindustrial times in our model are (1) the increase of CH$_4$ concentrations from 0.8 to 1.7 ppmv, (2) emissions of CO, NMHCs, and NO$_x$ from fuel combustion and industry, and (3) emissions from biomass burning. We conducted three sensitivity simulations in which each forcing was individually added to the standard preindustrial simulation. We also conducted two additional sensitivity simulations in which the changes in emissions from preindustrial times to today were applied to either CO and NMHCs or to NO$_x$. The global mean OH concentrations for these simulations are shown in Table 1, and global budgets of tropospheric O$_3$ are shown in Table 2.

As discussed in section 3, OH concentrations reflect a balance between sources of CO and hydrocarbons (S$_C$) which deplete OH and sources of NO$_2$ (S$_N$) which enhance OH. Table 1 shows values of S$_C$ and S$_N$ for our different simulations. In an analytical solution to a simple box model, we find that OH concentrations vary as S$_N$/S$_C$ (see appendix). Our global three-dimensional model indeed exhibits a linear dependence of the global mean OH concentration on the S$_N$/S$_C$ ratio for the range of simulations conducted (Figure 5), but the large intercept of the linear regression line implies a much smaller OH sensitivity to S$_N$/S$_C$ than implied by the box model analysis. This dampening of the OH sensitivity to S$_N$/S$_C$ in the global model reflects short lifetimes of NO$_x$ and fast-reacting NMHCs. Anthropogenic NO$_x$ and NMHCs emitted at the surface are mostly removed from the atmosphere within the continental boundary layer [Liang et al., 1998], which limits their impact on the global mean OH concentration. As seen in Table 1, increasing preindustrial CO and NMHC emissions to those of today (case B) increases S$_C$ by 70% but decreases the global mean OH concentration by only 30%; increasing preindustrial NO$_x$ emissions to present-day values (case C) increases S$_N$ by a factor of 4.5 but only increases OH by 40%. The less than 10% change of the global mean OH concentration since preindustrial times in our standard model reflects the relative constancy of the S$_N$/S$_C$ ratio (Figure 5) despite factors of 4.7 and 2.5 increases in S$_N$ and S$_C$, respectively.

The global increase of O$_3$ production in the model from preindustrial times (39 x 10$^{12}$ mol yr$^{-1}$) to present (85 x 10$^{12}$ mol yr$^{-1}$) reflects a combination of increasing emissions of NO$_x$, CO, and hydrocarbons. Although the O$_3$ production rate is NO$_2$ limited throughout the troposphere [Chameides et al., 1992], we find that the increase of NO$_x$ emissions alone (case C) accounts for only 57% of the increase in O$_3$ production.

![Figure 5](image)

Figure 5. Global mean OH concentration as a function of S$_N$/S$_C$ (moles yr$^{-1}$)$^{-1/2}$. The solid line shows a least squares fit. Model sensitivity simulations are described in Table 1.

Increases in CO and NMIIC emissions (case B) and in the concentration of CH$_4$ (case A) make significant contributions of about 15% each, because increasing CO and hydrocarbons enhances the O$_3$ production efficiency per unit NO$_x$ emitted [Lin et al., 1988; Crutzen, 1994].

One can separate the effects of anthropogenic emissions by source category. We find that emissions from fuel combustion and industry (case D) and from biomass burning (case E) each explain about 40% of the total increase of O$_3$ production in the model, while the increase of CH$_4$ concentrations (case A) explains most of the remaining 20%. This near-additivity reflects the constancy in the O$_3$ yield per unit of CO or hydrocarbon emitted, as discussed below. Fuel combustion and biomass burning make similar contributions to the rise in O$_3$ production even though the fossil fuel source of NO$_x$ is larger (Table 1) because of a higher O$_3$ production efficiency in the tropics where most of the biomass burning source is located.

The increase of O$_3$ production since preindustrial times can be related quantitatively to emissions of O$_3$ precursors by using as diagnostic the O$_3$ production efficiency ($\alpha_3$) per unit NO$_x$ emitted [cf. Liu et al., 1987] and the O$_3$ yield ($\gamma_3$) per unit of CO or hydrocarbons oxidized [Crutzen, 1988]. The losses of CO and hydrocarbons are in balance with their sources on a global scale. The global rate of chemical O$_3$ production ($P_{O3}$) is therefore

$$P_{O3} = \alpha_3 S$$

where $\alpha$ is $\alpha_N$ or $\alpha_C$ and $S$ is the source of NO$_x$ (S$_N$) or of CO and hydrocarbons (S$_C$), respectively. We obtain S$_C$ from Table 1 by adding the sources of CO, CH$_4$, and NMIICs. Table 2 shows global values of $\alpha_N$ and $\alpha_C$ for all the model simulations.

We find that the O$_3$ production efficiency $\alpha_N$ has decreased by a factor of 2 since preindustrial times because of its sensitivity to NO$_x$ concentrations [Liu et al., 1987]. By contrast, the O$_3$ yield $\alpha_C$ has changed little since preindustrial times; as a result, O$_3$ production has increased proportionally to S$_C$. [Insert Table 1 and Table 2 here for data.]
Using a lower limit of 0.2 for $\alpha_C$, we can also demonstrate simply that the rate of $O_3$ production must be NO$_x$ limited on a global scale. Ozone production is NO$_x$ limited if the source $S_{NOX}$ of HO$_x$ radicals is larger than the source $S_N$ of NO$_x$; it is hydrocarbon limited if the opposite holds [Jacob et al., 1993; Kleinman et al., 1997]. The dominant global source of HO$_x$ in the troposphere is $O_3$ photolysis to O($^1D$) followed by reaction of O($^1D$) with H$_2$O; this reaction is also a major sink for O$_3$ and amounts to 50-60% of the tropospheric O$_3$ source [Crutzen, 1994]. We thus estimate a minimum $S_{NOX}$ of 0.2 $S_C$ with an $\alpha_C$ of 0.2. In comparison, $S_{NOX}=0.013$ $S_C$ for the preindustrial atmosphere, $S_N=0.061$ $S_C$ for fossil fuel combustion, and $S_B=0.036$ $S_C$ for biomass burning (Table 1). The dominance of $S_{NOX}$ over $S_N$ implies that tropospheric O$_3$ production has remained NO$_x$ limited since preindustrial times and will stay so in the future as long as the global $S_N/S_C$ ratio remains below 0.1.

6. Conclusions

We examined the changes in tropospheric O$_3$ and OH concentrations since preindustrial times using a global three-dimensional model. The model has been shown previously to provide a generally good simulation of $O_3$, CO, NO$_x$, and the global mean OH concentration for the present atmosphere [Wang et al., 1998b]. Our simulation of the preindustrial atmosphere assumes 0.8 ppbv CH$_4$, no emissions from fuel combustion and industry, 10% of the present-day biomass burning source, and the same natural emissions (lightning, soils, and vegetation) as in the present.

Comparison of model results for the preindustrial atmosphere with reconstructed observations of O$_3$ in the nineteenth century shows significant discrepancies. The reconstructed data for O$_3$ over Europe and South America show concentrations of 7-12 ppbv; model results are about 5 ppbv higher and show a stronger seasonal variation. Previous global model simulations of O$_3$ in preindustrial times show similar overestimates. Allowing for some emissions from fossil fuel combustion in the nineteenth century would worsen the overestimates.

Of particular concern is the failure of the model to reproduce the low preindustrial O$_3$ observations at Pic du Midi (2.4 km altitude) which should not be affected by depositions effects or negative measurement interference by SO$_2$ or NH$_3$. A remarkable feature of the Pic du Midi observations is the lack of vertical gradient relative to sea level observations during the same period at nearby Montsouris. This lack of vertical gradient is inconsistent with our current understanding of tropospheric O$_3$. Matching the Pic du Midi observations in the model would require an important missing sink for O$_3$ in the preindustrial atmosphere or a downward revision of lightning NO$_x$ emissions (presently 3 Tg N yr$^{-1}$) which provide the principal source of preindustrial O$_3$.

Polar ice core data for preindustrial times are available for CO, CH$_3$O (proxy of OH), and H$_2$O$_2$ (proxy of HO$_x$). The model underestimates the ice core measurements of nineteenth century CO concentrations and corresponding stratospheric gradient [Hann et al., 1996]. These measurements cannot be reconciled with any reasonable CO emission inventories for the nineteenth century. Model results for O$_3$ concentrations over Greenland indicate a decrease of 12% since preindustrial times, comparable with the 30% decrease derived from ice core records of CH$_3$O. Model results for
H$_2$O$_2$ concentrations over Greenland indicate a factor of 2.5 increase since preindustrial times; ice core records show little change of H$_2$O$_2$ concentrations until 1970 and a doubling since then.

We find that anthropogenic emissions since preindustrial times have caused an increase of 120% in tropospheric O$_3$ production and a doubling of the total tropospheric O$_3$ source (including transport from the stratosphere). The increase in the global tropospheric O$_3$ burden is only 63% because O$_3$ production due to anthropogenic emissions takes place preferentially in the lower troposphere, where the lifetime of O$_3$ is shorter than in the middle and upper troposphere.

Although the local rate of O$_3$ production in the troposphere is NO$_x$ limited in general, we find that increasing NO$_x$ emissions alone from preindustrial times to present explains only 57% of the rise in O$_3$ production of the global troposphere. Increasing emissions of CH$_4$, CO, and NMHCs accounts for the rest because the O$_3$ production efficiency per mole of NO$_x$ emitted increases with increasing CO and hydrocarbons. Separating the effects of anthropogenic emissions by source category, we find that fossil fuel combustion and the increase of biomass burning each contribute about 40% of the global increase of O$_3$ production since preindustrial times in the model and that the increase of atmospheric CH$_4$ contributes about 20%.

The global O$_3$ production efficiency $\omega_N$ per unit NO$_x$ emitted decreases in the model from 60 mol/mol in preindustrial times to 28 mol/mol at present reflecting a greater relative increase of NO$_x$ emissions (factor of 4.7) than of CO and hydrocarbons (factor of 2.5). The global O$_3$ yield $\omega_C$ per unit CO or hydrocarbon oxidized has, however, remained nearly constant at 0.7-0.8 mol/mol; the emission mixes of NO$_x$, CO, and hydrocarbons from fuel combustion and industry and from biomass burning are such that they conserve $\omega_C$ but not $\omega_N$. The increase of tropospheric O$_3$ production since preindustrial times has therefore largely followed that of CO and hydrocarbon emissions.

Model results indicate that the global mean OH concentration (weighted by air mass) has decreased by 9% since preindustrial times. However, the lifetime of CH$_3$CCl$_3$ against OH oxidation has remained at 5.1 years because of the temperature dependence of the oxidation rate constant; the increase of OH concentrations in the warmer lower troposphere has compensated for a lower global mean OH concentration. We find that the global mean OH concentration varies linearly with the $S_N^2/S_C^{3/2}$ ratio, where $S_N$ and $S_C$ are the total tropospheric sources of NO$_x$ and of CO and hydrocarbons, respectively. The relative constancy of the global mean OH concentration since preindustrial times reflects conservation of the $S_N^2/S_C^{3/2}$ ratio by anthropogenic emissions.

Appendix: A Simple Schematic for Tropospheric O$_3$ and HO$_x$ Chemistry

We consider here a simple schematic of tropospheric O$_3$-NO$_x$-CO chemistry derived from currently accepted mechanisms [Logan et al., 1981]. The primary supply of HO$_x$ (OH + HO$_2$) radical is the photolysis of O$_3$ to O(1D) and subsequent reaction of O(1D) with H$_2$O.

(R1) \[ \text{O}_3 + h\nu \rightarrow \text{O}(1D) + \text{O}_2 \]

(R2) \[ \text{O}(1D) + \text{M} \rightarrow \text{O}_3 + \text{M} \]

(R3) \[ \text{O}(1D) + \text{H}_2\text{O} \rightarrow 2 \text{OH} \]

Cycling of HO$_x$ by oxidation of CO in the presence of NO$_x$ leads to production of O$_3$.

(R4) \[ \text{CO} + \text{OH} \rightarrow \text{CO}_2 + \text{HO}_2 \]

(R5) \[ \text{HO}_2 + \text{NO} \rightarrow \text{OH} + \text{NO}_2 \]

(R6) \[ \text{NO}_2 + h\nu \rightarrow \text{NO} + \text{O}_3 \]

The oxidation of NO to NO$_2$ also takes place by the reaction NO + O$_3$.

(R7) \[ \text{NO} + \text{O}_3 \rightarrow \text{NO}_2 + \text{O}_2 \]

Loss of HO$_x$ radicals takes place mostly by self-reaction of HO$_2$ and oxidation of NO$_2$ by OH.

(R8) \[ \text{HO}_2 + \text{HO}_2 \rightarrow \text{H}_2\text{O}_2 + \text{O}_2 \]

(R9) \[ \text{OH} + \text{NO}_2 \rightarrow \text{HO}_2 + \text{NO}_3 \]

We consider in this system the steady state equations for HO$_x$, OH, O$_3$, NO$_x$, and CO concentrations, respectively,

\[ \frac{2 \cdot J_1 \cdot k_2 \cdot [\text{H}_2\text{O}]}{k_4 \cdot [\text{M}]} \cdot [\text{O}_3] = 2k_3 \cdot [\text{HO}_2]^2 + k_4 \cdot [\text{OH}] \cdot [\text{NO}_2] \cdot [\text{M}] \] \hspace{1cm} (A1)

\[ k_4 \cdot [\text{HO}_2] \cdot [\text{NO}] + 2 \cdot \frac{J_1 \cdot k_5 \cdot [\text{H}_2\text{O}]}{k_2 \cdot [\text{M}]} \cdot [\text{O}_3] = k_4 \cdot [\text{OH}] \cdot [\text{CO}] \] \hspace{1cm} (A2)

\[ k_2 \cdot [\text{HO}_2] \cdot [\text{NO}] + F_{\text{O}_3} = \frac{J_1 \cdot k_3 \cdot [\text{H}_2\text{O}]}{k_2 \cdot [\text{M}]} \cdot [\text{O}_3] + k_d \cdot [\text{O}_3] \] \hspace{1cm} (A3)

\[ S_N = k_9 \cdot [\text{OH}] \cdot [\text{NO}_2] \] \hspace{1cm} (A4)

\[ S_C = k_4 \cdot [\text{OH}] \cdot [\text{CO}] \] \hspace{1cm} (A5)

where $J_1$ or $J_2$ is the reaction or photolysis rate constant for reaction 1 or 2; $k_d$ is a deposition rate constant for O$_3$, $F_{\text{O}_3}$ is the net transport rate of O$_3$ from the stratosphere, and $S_N$ and $S_C$ are the sources of NO$_x$ and CO, respectively. Hydrocarbons react similarly to CO and their sources are lumped into $S_C$ for the purpose of this simple model. Since $S_C$ is much larger than $S_N$ in either the present or preindustrial atmosphere (Table 1), loss of OH radicals through reaction (R9) is negligible compared to reaction (R4) and is neglected in equation (A2).

We can now derive the chemical production rate of O$_3$ as that of the odd-oxygen family (O$_3$ = O$_3$ + O + NO$_2$) by using equations (A2), (A3), and (A5),

\[ P(\text{O}_3) = k_5 \cdot [\text{HO}_2] \cdot [\text{NO}] = \frac{1}{3} \left( S_C - 2 \cdot F_{\text{O}_3} \cdot k_d \cdot [\text{O}_3] \right) \] \hspace{1cm} (A6)

This chemical system is stable only if sufficient OH is available to oxidize CO. Methane observations show that the atmosphere has been stable in this manner over at least the 200,000 year extent of the ice core records [IPCC, 1996]. To satisfy this stability in our simple model, the production of O$_3$ must be at least

\[ P_{\text{O}_3}(\text{min}) = \frac{1}{3} \left( S_C - 2 \cdot F_{\text{O}_3} \right) \] \hspace{1cm} (A7)
At this limit, all $O_3$ molecules produced in the troposphere or transported from the stratosphere are used to generate OH radicals (R3) for the oxidation of CO (R4). In the real atmosphere, the lower limit for $P(O_3)$ is higher than that given by equation (A7) because (1) additional $O_3$ sinks include the reactions of $O_3$ with OH and HO$_2$, (2) additional OH sinks include the reactions of OH with $O_3$, H$_2$O$_2$, and H$_2$, and (3) additional $O_3$ production takes place through the reaction of NO and organic peroxy radicals in which no OH production takes place unlike in reaction (R5). Another stable chemical regime may also exist when NO emission is extremely low and the HO$_2$ sources from photolysis of carbonyl compounds and the chemical recycling of peroxides become more important than the HO$_2$ source from $O_3$ (reactions R1–R3). The concentrations of $O_3$ and OH would be extremely low under these conditions. Such a regime is not considered in this analysis.

Equation (A7) implies the existence of a lower limit for the $O_3$ yield $\alpha_C$ per unit of CO or hydrocarbons emitted,

$$\alpha_C(\text{min}) = \frac{1}{3} (1 - 2 F_{O_3} / S_C)$$  \hspace{1cm} (A8)

Estimates of $S_C$ and $F_{O_3}$ for preindustrial and present atmospheres (Table 1) yield a lower limit of 0.2 for $\alpha_C$.

The maximum value of $\alpha_C$ corresponding to high-NO$_x$ conditions, is 1 for oxidation of CO to CO$_2$, 1.7 for oxidation of CH$_4$ to CO, and about 1 per atom C for oxidation of NMHCs to CO (Crutzen, 1988). For the CO and hydrocarbon emission mix corresponding to the preindustrial and present atmospheres, we obtain a maximum value of 3 for $\alpha_C$. The total source of $O_3$ in the troposphere thus scales to $S_C$ with a factor of $\alpha_C$ that may vary theoretically from 0.2 to 3.

The above schematic also yields a relationship between OH concentrations, $S_N$, and $S_C$. Considering equations (A1)-(A5) and assuming $O_3$-NO$_2$/NO$_2$ photochemical steady state by reactions (R6)-(R7), we obtain

$$[OH] = \frac{[II_2O] \times S_N}{(S_C - 2(F_{O_3} - k_d[O_3]))(S_C + F_{O_3} - k_d[O_3])^{1/2}}$$  \hspace{1cm} (A9)

Since $S_C$ is much larger than $F_{O_3}$ in both preindustrial and present atmospheres (Table 1), this equation can be reduced to a simple dependence of [OH] on $S_N$ and $S_C$:

$$[OH] = K \frac{S_N}{S_C^{3/2}}$$  \hspace{1cm} (A10)

where $K$ is a constant. Results from our global three-dimensional model show a linear relationship between the global mean OH concentration and the $S_N/S_C^{3/2}$ ratio, but the actual dependence of [OH] on $S_N/S_C^{2/3}$ is much less than implied by the present simple box model analysis (section 5).
